We study a multiple invasion model to simulate corrosion or intrusion processes. Estimated values for the fractal dimension of the invaded region reveal that the critical exponents vary as function of the generation number $G$, i.e., with the number of times the invasion process takes place. The averaged mass $M$ of the invaded region decreases with a power-law as a function of $G$, $M \sim G^{-\beta}$, where the exponent $\beta \approx 0.6$. We also find that the fractal dimension of the invaded cluster changes from $d_1 = 1.887 \pm 0.002$ to $d_4 = 2.127 \pm 0.005$. This result confirms that the multiple invasion process (for the case in which un-invaded regions are forbidden) follows a continuous transition from one universality class (NTIP) to another (optimal path). In addition, we report extensive numerical simulations that indicate that the mass distribution of avalanches $P(S,L)$ has a power-law behavior and we find that the exponent $\tau$ governing the power-law $P(S,L) \sim S^{-\tau}$ changes continuously as a function of the parameter $G$. We propose a scaling law for the mass distribution of avalanches for different number of generations $G$.

I. INTRODUCTION

The veins of gems and ores are often the product of a multiple intrusion of a reacting fluid into a porous soil in which dissolution and subsequent re-crystallization processes are the determining factor. Some examples like porphyry copper deposits [1] or olivine [2] have been studied in the literature and it is known that the surviving network of ore deposits has a fractal structure [3, 4] that can be exploited for mineral exploration [5]. A similar situation can be found in vulcanology when magma is repeatedly injected through the same pathway, each time melting up again the most recent formations to find its way out [6].

The evolution of the pore structure after several invasion-frost-thaw events has been investigated numerically [7], and results indicate that the fractal dimension of invasion clusters varies with the number of invasion cycles. In this work, after invasion takes place, the structure of the porous pathway is randomly healed. In a similar approach [8], an optimized version of the multiple invasion percolation model was studied. Some topological aspects as the acceptance profile and the coordination number were investigated and compared to those of ordinary invasion percolation.

In the cases mentioned [1–5] above and also in other cases of repeated invasions of corroding, dissolving or melting fluids into a strongly heterogeneous substrate, slowly consolidating matrix fractal patterns are created that reflect the history of the material. It is the aim of this paper to develop a model of multiple invasion in order to simulate how these patterns form and how their fractal dimension changes. In fact, we propose a complete theoretical framework based on scaling laws [6].

The basis mechanism behind the multiple invasion processes in rock evolution is the following: A first invasion takes place within a geologically speaking very short time and leaves behind a certain damaged region (which typically has a fractal shape). Then during a long period nothing dramatic happens so that e.g. crystallization or diverse chemical processes can take place. In this way slowly the material is again strengthened partly repairing the damaged region. Then suddenly due to some tectonic mechanism like an earthquake or volcanic activity again an invasion takes place. It will favorably follow along the weakest regions of the solid which typically be along previously damaged regions. The interest in the problem is to understand to which degree this reinvasion will either fully or only partially coincide with the first one. The process of reinvasion can be repeated many times and only the final product is observed at the end like the scars of many wounds on the skin of an old animal.

The theory of avalanche dynamics has been studied in a variety of contexts, for example in growth models, interface depinning and invasion percolation [9]. The formation of fractal structures, diffusion with anomalous Hurst exponents and Lévy flights, can all be related to the same underlying avalanche dynamics [9]. Normally, the presence of avalanches in the invasion process supposes unchanged porous media. In this work we also investigate the mass-distribution of avalanches and determine how the exponent that characterizes this distribution changes for different cycles of the invasion process. This paper is organized as follows. In Section II, we present the model and simulate the multiple invasion in consolidating medium for the case in which un-invaded regions are forbidden. In Section III we show the results for the invaded cluster mass. The results and analysis of the numerical simulation for avalanche distribution are shown in Section IV. In Section V we present simulation results of the multiple invasion model for the case where the non-invaded regions are not completely forbidden, while the conclusions are presented in Section VI.
FIG. 1: Typical cluster for different generations on a 256 × 256 lattice, for $p^* = 1$. The injection point is localized in the center of the lattice. In figures we show the results for $G = 1, 5, 10$ and 100, respectively.

II. MODEL

In order to simulate the injection process we use the standard non-trapping invasion percolation (NTIP) [10]. In this model the invaded solid is considered to be very heterogeneous and the invading fluid can potentially enter anywhere along the interface. Here the consolidating medium is represented conveniently as a square network. The sites of the lattice can be viewed as the smallest units of constant strength and the randomness of the strength of the medium is incorporated by assigning random numbers to sites. For simplicity, we consider the case in which dissolutions control the fluid invasion.

On our heterogeneous medium we start by applying the standard invasion process of NTIP. For completeness the algorithm is described as follows. Initially, let us assign a random number, $p_i$, drawn from a uniform distribution in the interval $[0,1]$, to each site $i$ of the lattice. We choose one site in the center of the lattice and occupy it. This site represents the injection point of the fluid and is the seed of the invading cluster. We look among the neighboring sites of this cluster (the growth sites) and choose the one which carries the smallest random number. This site is then invaded and added to the cluster. Then we increase the list of sites that are eligible to be invaded. At each step of the invasion process, the perimeter of the nearest neighbors of the sites that form the invading cluster is investigated and the site that has the smallest $p_i$ is chosen. This procedure is repeated until the edge of the lattice is reached. At this point the simulation stops and the mass $M$ (i.e., the number of sites belonging to the invaded cluster) of the cluster is computed. The number of sites of the invaded cluster is very often considered as a time parameter.

Now we present the new feature introduced to the standard invasion percolation. After we finish the above described simulation in agreement with customary NTIP, the simulation is performed again starting every time at the same injection point. New random numbers chosen from a uniform distribution in the interval $[0,1]$ are assigned to all sites belonging to the previously invaded cluster before a new invasion process starts. To all other sites, i.e., namely, those that are outside the cluster, we assign a random number homogeneously distributed in the interval $[p^*,1]$ where $p^*$ is a number close to unity. Compared to the support used in the first generation where all sites can be invaded, the second generation appears substantially reduced, because it mostly corresponds to the cluster invaded in the first generation. In this way we generate again an invasion cluster for which $p^* = 1$ is a subset of the previous one and so necessarily smaller. This procedure is repeated $G$ times, where $G$ is the number of generations. Standard invasion percolation coincides with the case $G = 1$. At each new generation $G$, the sites of the previous invasion are reinvaded.

Let us first consider the case $p^* = 1$. In this situation, the invaded cluster is after each time a subset of the previous one so that after a finite number of iterations the cluster does not decrease any longer. The number of generations needed to reach a cluster whose mass remains unchanged depends on the size of the original lattice, because the number of possible available sites is proportional to the system size. Therefore, the saturation number is different for each lattice size. In order to illustrate these changes in the structure after each process of invasion, we show in Fig. 1 typical clusters generated for a lattice of size $L = 256$ for four different generations $G$. Another important quantity is the probability distri-
FIG. 3: The evolution of the rate \( \frac{M_G}{M_{G-1}} \) as a function of the logarithm of the generation number \( G \) for \( p^* = 1 \). Here \( M_G \) is the mass at generation \( G \) for different sizes \( L = 64, 128, 256 \) and 512.

distribution of \( p_i \) of the invaded sites. In Fig. 2 we present the normalized distribution \( P_{inv}(p) \) for different generations \( G \) obtained from 1000 realizations of size \( L = 512 \). After the completion of the first invasion process, the distribution expectedly displays a transition at \( p \approx p_c \), where \( p_c \) is the critical site percolation point, \( p_c = 0.59275 \) for a square lattice\,[11]. The same behavior has been observed by numerical simulation in Refs.\,[7, 8]. For \( G = 2 \) the distribution \( P_{inv}(p) \) becomes flat and the profile does not change any more as function of \( G \). This happens because when \( G > 1 \) sites with larger \( p_i \) are also invaded.

III. CLUSTER MASS

In our simulations we used the NTIP algorithm for square lattices of sizes \( L = 64, 128, 256, 512 \) and 1024. For each value of \( G \), we perform simulations for 10000 realizations and compute the mass \( M_G \) of the invaded cluster. In Fig. 3, we show the ratio \( \frac{M_G}{M_{G-1}} \) as a function of the generation number \( G \). For each size \( L \), \( G \), is defined as the number of generations at which the mass of the invaded cluster reaches a constant value, i.e., for which \( \frac{M_G}{M_{G-1}} = 1 \). The results of our simulations shown in Fig. 4 for four values of the generation number \( G \), indicate that the mass \( M \) has a power-law dependence on the size \( L \), \( M \sim L^{d_G} \), where \( d_G \) is the fractal dimension of the invaded cluster. The case \( G = 1 \) corresponds to the standard invasion percolation model. The value obtained from our simulations, \( d_1 = 1.887 \pm 0.002 \), is in good agreement with the current estimate \( d_1 = 1.8959 \) for NTIP\,[11–14]. The results shown in Fig. 4 indicate that by increasing the generation number the fractal dimension decreases continuously until it reaches a saturation value of \( d_* = 1.217 \pm 0.005 \) at \( G_* \). This value agrees with the fractal dimension of the optimal path in the strong disorder limit \( d_{opt} = 1.22 \pm 0.01 \)[15]. As shown in Fig. 5 for large system sizes we find that the average mass of the invaded cluster asymptotically follows a power-law behavior

\[
M \sim G^3.
\] (1)

To better analyze the data, we normalize the mass by the constant \( M_1 \), which is the average mass of the invaded cluster at \( G = 1 \). Similar to some problems that involve growth surfaces\,[16], this process has two characteristic regimes: (i) power law evolution and (ii) saturation when \( G \to \infty \). To describe this behavior we propose the scaling relation\,[6]

\[
\frac{M(G,L)}{M_1} = L^\alpha f \left( \frac{G - N_0}{L^z} \right).
\] (2)

where \( N_0 \) is an off-set value for the generation number \( G \) and \( \alpha \) and \( z \) are scaling exponents. We assume that the scaling function \( f(x) \) has the form \( f(x) \sim x^\beta \) in the limit \( x \ll 1 \) and \( f(x) = \text{const} \) when \( x \gg 1 \). Furthermore, a direct relation among exponents \( \alpha, \beta \) and \( z \) can be obtained. We find \( M/M_1 \sim G^3 \) for \( L \gg 1 \) and, since \( M/M_1 \sim L^z \) in the saturation regime \( G \gg 1 \), we obtain that \( \alpha = d_* - d_1 \).

In the crossover region, when the fractal dimension goes from \( d_1 \) \((G = 1)\) to \( d_* \) \((G = G_*)\) we have

\[
(G - N_0) \sim L^z.
\] (3)

From these relations, we obtain that

\[
z = \frac{\alpha}{\beta},
\] (4)
and from the fact that the fractal dimension has reached the saturation value $d_s \approx 1.22$, it gives $\alpha = -0.68$. The inset of Fig. 5 shows the data collapse obtained by rescaling $M/M_1$ and $G$ according to the scaling form Eq. (2). In this case the best fit to the data gives $\beta \approx 0.6$. Substituting into Eq. 4 we find $z = 1.13$.

IV. AVALANCHE DISTRIBUTION

It has been known since a long time that avalanches occur in invasion percolation and that these avalanches obey scaling relations related to percolation theory [17]. An avalanche occurs when a site $j$ is invaded at a value $p_j$ and then a series of sites $i$ connected to this original site are sequentially invaded with $p_i < p_j$. It is also known that the system reaches a self-organized critical state characterized by avalanches of all sizes distributed according to a power law. In the case of NTIP, the exponent corresponding to the power law behavior for the distribution $P(S)$ of avalanche sizes $S$ is $\tau = 1.527$ [17].

In our simulation we found that the exponent corresponding to the case $G = 1$ is $\tau = 1.46 \pm 0.03$. The expected value [17] is outside of our error bars, which we attribute to the fact that we have not reached the asymptotic limit because our systems are too small.

We performed simulations for different generations $G$ on lattices of sizes $L = 64, 128, 256, 512$ and 1024, and calculated the size distribution of avalanches. In Fig. 6 we show $P(S)$ for size $L = 512$ and $G = 2, 4, 8, 16, 32, 64$ and 128. It is clear from this figure that $P(S)$ displays power-law behavior with exponent dependent of the number of generations $G$. The solid lines indicate the slopes in the two limit cases $G = 1$ (lower) and $G = 128$ (upper).

In Fig. 7, we show how the exponent of the power-law $\tau$ changes as function of the number of generations $G$. For large values of $G$ the exponent converges to $\tau = 1$. This value is the same found for the distribution of avalanches $P(S)$ in the one-dimensional case [18]. This is consistent with Fig. 1 for $G = 100$ where the avalanche process is limited to a thin path that is essentially an one-dimensional topology.

In Figs. 8(a) and 8(b) we show the log-log plot of the distribution of avalanche sizes. It is clear from these figures that $P(S)$ displays a scaling region for intermediate avalanche sizes. In addition the scaling region is followed by a sudden cut-off that decays faster than exponential due to a finite size effect. The range of the power-law region is proportional to the lattice size. As a consequence the biggest avalanches occur in the largest lattice. The position of the cutoff depends on $G$ for fixed $L$. We propose a scaling form for the mass distribution $P(L, S)$, which accounts for finite size effects and power-law behavior [19]

$$P(S, L) \propto S^{-\tau} f \left( \frac{S}{L^\gamma} \right),$$  

where the function $f(x)$ has a Gaussian form

$$f(x) = e^{\exp[-x^2]}.$$  

In practice, the appropriate parameters of the scaling function Eq. (5) have been determined here through a
nonlinear fitting procedure of the function
\[ P(S, L) = A_0 S^{-\gamma} \exp[-(S/A_1)^2] \]
(7)
to the avalanche data. We observe that both the prefactor \( A_0 \) and the crossover amplitude \( A_1 \) depend on the system size.

The solid line in Fig. 9 corresponds to the best fit using Eq. (7) for \( G = 2 \) and many different sizes \( L \) with \( \gamma = 1.37 \). The inset of Fig. 9 shows the power-law dependence of crossover amplitude on the system size, \( A_1 \propto L^\gamma \). The straight lines are the least-square fits to the data, with the slopes corresponding to the exponent \( \gamma \) in Eq. (5) for different generation numbers.

In Fig. 10 we plot the exponent \( \gamma \) versus \( G \), and see that the exponent has a monotonic behavior as function of the generation number.

In Fig. 11 we show the rescaled function \( P(S/L^{\gamma}) \) for \( G = 16 \). The data collapse obtained confirms the validity of the scaling form of Eq. (7). This confirms that the system is self-organized critical and the rescaled distribution shows the asymptotic scaling behavior of Eq. (7).

V. RESULTS FOR \( p' \neq 1 \)

In the first part of this work we considered \( p' = 1 \). Now we present simulations for different \( p' \) very close to unity. In Fig. 12 we show how the mass of the invaded cluster varies as function of the generation number \( G \) for a typical realization of the multiply invasion process. In the case \( p' = 0.9 \) the value of the mass shows strong fluctuations. If the probability to occupy sites outside of the previously invaded cluster is raised, the previous invaded region of the porous media is more likely invaded.

To understand the qualitative behavior of the invaded cluster as function of the generation \( G \) we show in Figs. 13 and 14, typical clusters for two values \( p' = 0.9 \) and \( p' = 0.999999 \), for five different generations \( G = 1, 5, 10, 25 \) and 50. For \( p' = 0.9 \), the cluster is more compact and sometimes changes the point where it reaches the border. When \( p' = 0.999999 \), the cluster becomes smaller at each generation.

In order to be more quantitative we calculate the fractal dimension \( d_f \). We measure the mass of the invaded cluster for different generations \( G \) for two different probabilities \( p' = 0.9 \) and 0.999999. Numerical simulations were carried out for 1000 realizations on lattice sizes \( L = 64, 128, 256 \) and 512. In Figs. 15 and 16 we present log-log plots of the averaged mass of the invaded cluster versus the lattice size \( L \). The linear fit to the data yields the fractal dimension \( d_f \) of the invaded cluster. In the
case $p^* = 0.9$, the fractal dimension is $d_f = 1.90 \pm 0.01$ for all generations. For $p^* = 0.999999$ the fractal dimension decreases when $G$ increases. This implies that the fractal dimension of the invaded cluster has a behavior similar to the previously studied case in which $p^* = 1$.

VI. CONCLUSIONS

We have presented a comprehensive model to study a multiple invasion process. We have shown that the mass $M_G$ of the invaded cluster decreases with the generation number $G$. In addition, the fractal dimension of the invaded cluster changes from $d_f = 1.887 \pm 0.002$ to $d_f = 1.217 \pm 0.005$ corresponding to $G = 1$ and $G = G_s$, respectively. This result confirms that the multiple invasion process follows a continuous transition from one universality class (NTIP) to another (optimal path). We confirmed by extensive simulations that the invaded mass follows a power law $M \sim G^\beta$ with an exponent $\beta \approx 0.6$. In addition the probability distribution of avalanches sizes $P(S,L,G)$ has been studied for different system sizes as function of the parameter $G$. We found that the mass distribution of avalanches follows a power law where the exponent $\tau$ changes as function of the generation number $G$. Based on this fact, we suggest that the avalanche process belongs to a different universality class for each $G$ since no crossover scaling seems possible. Our results also indicate that this change in universality class occurs in a continuous way. Concerning the re-invasion of crystallizing, solidifying or healing fluids we conclude that only in the case in which the non-invaded part is not substantially damaged and the healed parts typically do not get much stronger than they were before the invasion, the multiple invasion process converges well to a different universality class, namely that of the optimal path [13]. In the opposite case corresponding to $p^* \neq 1$, the
